Abstract: Dicarba-closo-dodecaboranes (or carboranes) are icosahedral clusters of empirical formula $\text{C}_2\text{B}_{10}\text{H}_{12}$. Depending on the relative position of the carbon atoms in the cluster, three isomers can be distinguished: ortho- (1,2), meta- (1,7) and para- (1,12). Our group focused this research on the first two: ortho- and meta-carborane isomers. The high symmetry, remarkable stability and versatile reactivity of these clusters allow their functionalization according to a desired application. Our group and others were interested in carboranylphosphorus compounds, mostly due to their properties as ligands for organometallic chemistry and enantioselective catalysis. Among them are carboranylphosphines and carboranylphosphines with P(V) moieties, except carboranyl phosphinates and carboranyl phosphonates. Few studies are found in the literature on carboranyl phosphinic and phosphonic acids. Our research goal has been devoted to developing preparation and characterization of carboranyl phosphinates, aiming towards the designing of purely inorganic ligands that are capable to coordinate to metals producing stable water-soluble polynuclear systems. The influence of the boron cluster on the reactivity of the phosphinate group was studied as well.

Keywords: Carboranes, phosphinates, phosphonates.

Introduction

In the periodic table of elements, boron lies next to carbon. Both boron and carbon have the property of catenating. Carbon forms cycles and polymers and is the base of organic chemistry. Boron forms clusters and induces a huge discipline of chemistry: Boron science. Boranes, boron clusters and, in particular, icosahedral dicarba-closo-dodecaboranes with empirical formula $\text{C}_2\text{B}_{10}\text{H}_{12}$ are of special interest. Boron clusters were considered as electron deficient compounds till Lipscomb’s discovery. William N. Lipscomb was awarded with the Nobel Prize in Chemistry 1976 "for his studies on the structure of boranes illuminating problems of chemical bonding". Lipscomb proposed the mechanism to understand the three-center two-electron (3c-2e) bond in boron clusters [1]. In 3c-2e, a pair of electrons is shared between three atoms. The three atoms can be a boron atom at either end and a hydrogen atom in the middle, as in the case of the diborane $\text{B}_2\text{H}_6$ bond, or the three atoms, can be three boron atoms, as in the polyhedral clusters. 3D aromaticity of boron or boronate clusters gives them unique properties that are not common in organic chemistry [2].

A relation between hydrocarbon and borohydride chemistries has been recently reported [3]. The idea is based on keeping...
the same number of valence electrons in a confined space. Thus, the addition of an extra electron to each boron atom in borohydrides yields molecular analogues of hydrocarbons. As a result, for any given hydrocarbon in organic chemistry, its borohydride analogue can be found in boron chemistry. Along this line, work was recently reported that establishes a direct connection between Wade-Mingos rule of tridimensional aromatic closo boron hydride clusters and Hückel’s rule of planar aromatic annulenes, showing that they share a common origin regulated by the number of valence electrons in an electronic confined space [4].

Chemical reactivity of ortho- and meta-carboranes: electrophilic substitutions on ortho- and meta-carboranes

Although ortho- and meta-carborane clusters are remarkably stable, in certain reaction conditions they exhibit high synthetic reactivity. From the point of view of electrophilic substitution at the C−H vertices (C: carbon atom belonging to carborane cluster), both isomers display similar chemical reactivity. In both carborane isomers the hydrogen atoms of the C−H units are more acidic than the ones bonded to B−H vertices, due to the more electropositive character of carbon with respect to boron (2.5 and 2.0, respectively, according to the Pauling scale). Thus, hydrogen atoms attached to carbon can be considered acidic while those bonded to boron are considered hydride. The acidity of the C−H vertices decreases in the order of ortho-, meta- and para-carborane. Its vulnerability to become deprotonated decreases in the same order.

This relatively acidic character of C−H units allows their deprotonation by strong alkali and alkaline earth metal bases, like for example n-butyllithium or Grignard reagents. The generated negative charge on the carbon atom of the cluster, C, attracts electrophilic reagents, opening the way to the introduction of functional groups at the C position of the cluster.

Figure 2 shows the two possible pathways for substitutions at one or both of the C atoms. After dilithiation of the carborane cluster (bottom pathway) it is possible to introduce simultaneously twice the same substituent, which leads to symmetrically substituted carborane. The other pathway (top) demonstrates monosubstitution of the carborane cluster or unsymmetrical disubstitution. The synthesis of monosubstituted carborane derivatives is more complicated compared to the synthesis of disubstituted carborane derivatives. The reason is the disproportionation of Li[1,2−C2B10H11] into Li2[1,2−C2B10H10] and 1,2−C2B10H10, as it was found for ortho-carborane [5]. Several approaches have been developed to overcome this problem. They include the use of protection/deprotection methods.
ologies with dimethoxyethane as the solvent or by doing the reaction at high dilution [6]. Perhaps a simpler method is performing the monosubstitution reactions in ethereal solvents at low temperature and specific carborane concentration. It was suggested that, depending on the type of electrophile, it is possible to find a combination of conditions (ethereal solvent, temperature, carborane concentration) that facilitates the largest degree of monosubstitution [7].

Phosphorus-substituted carboranes and carboranyl phosphinic acids

Substituting conventional organic entities by boron clusters to produce new compounds could deliver remarkable properties such as high rigidity and space occupancy. Carboranylphosphines is one example [8]. Phosphines are prominent ligands in coordination chemistry. By changing groups bonded to phosphorus, the steric and electronic effects are modified, so it is possible to «tailor» properties of the phosphines as ligands.

Our group and others were interested in the exploration of the properties of phosphinate ligands synthesized on the ortho-carborane platform [8], including P(III) and P(V) derivatives of ortho-carboranylphosphines [9]. The first derivatives that contain pentavalent phosphorus, phosphinic acids of ortho- and meta-carboranes were synthesized many years ago [10]. However, neither their characterization nor reproducible procedures of their synthesis were available. As a consequence, their coordination chemistry still remained unexplored till recently [11]. A representative drawing of the carboranyl phosphines, carboranyl phosphate oxides, carboranyl phosphinates and carboranyl phosphonates is shown in Figure 3.

Synthetic pathway of carboranyl phosphinic acids

As previously mentioned, due to the acidic character of C–H vertices of the cluster, they can be deprotonated with strong bases and then functionalized by means of electrophilic reagents. In our case, the deprotonation of the meta-carborane clusters 1–2 by n-BuLi followed by reaction with ClP(NMe₂)₂ gave closo-carboranyldiaminophosphine derivatives 3–4. The reaction of compounds 3–4 with dry HCl gas in benzene gives closo-carboranyldichlorophosphines 5–6 that can be further hydrolyzed to the corresponding phosphinic acids 7–8 in aqueous solution at room temperature. The general reaction is given in Scheme 1.

Compounds 3–10 were characterized by multinuclear NMR and FT-IR spectroscopic techniques, mass spectrometry and elemental analysis. Table 1 shows the ³¹P chemical shifts of
these phosphorus compounds derived from ortho- and meta-carborane, which appear in the region between $\delta +162.20/14.66$ ppm. The $^{31}$P resonances in all ortho-carborane derivatives appear at higher frequency compared with those of the meta-carborane derivatives. From Table 1, it is clear when comparing the two cluster isomers that the difference in the $^{31}$P chemical shift is the same: entries 1 and 2, entries 4 and 5 or entries 7 and 8. These experimental data display that a P(V) atom bonded to a meta-carboranyl cluster is more deshielded than if it is bonded to an ortho-carboranyl one; the difference being 6.45, 6.82 and 3.70 ppm, respectively. The same trend is observed in the anionic sodium salts, entries 10 and 11.

</table>
and 11. It is also important to note when comparing entries 2 and 3, entries 5 and 6 or entries 8 and 9 on Table 1 that there is no influence on the nature of the R group (R = Me, H) bonded to the second C, the difference being 0.11 ppm in all cases. There is no difference in the chemical shifts for the sodium salts, entries 11 and 12.

Closo-carboranylphosphinic acids, compounds 7–9, displayed a singlet around 17 ppm (for ortho-isomer) and 21 ppm (for meta-isomer) on $^{31}$P{H} NMR spectrum that turns to a doublet in the $^{31}$P NMR spectrum with coupling constant in the range of $^1J(P, H) = 635$ Hz, indicating the presence of a P–H bond in the compounds.

**Isotopic exchange with deuterium and tautomerization**

It is well known that pentavalent phosphinic acid derivatives R(O)PH(OH) are involved in the tautomerization process with the corresponding trivalent phosphonous acid form RP(OH)$_2$ [12]. This tautomeric equilibrium (Figure 5) is completely shifted to P(V) tautomer, so free phosphonous acid normally cannot be detected by spectroscopic methods.

It was suggested that phosphorus-bonded hydrogen of phenylphosphinic acid undergoes isotopic exchange with deuterium from the deuterated solvent due to the presence of tautomeric equilibrium [13]. The compounds 1–OPH(OH)–1,7–...
C\textsubscript{2}B\textsubscript{10}H\textsubscript{11} (8), Na[1–Me–7–OPH(O)–1,7–C\textsubscript{2}B\textsubscript{10}H\textsubscript{10}] (9), and Na[1–OPH(O)–1,7–C\textsubscript{2}B\textsubscript{10}H\textsubscript{11}] (10) display the same isotopic exchange.

To know the influence of the meta-carboranyl ligand, the kinetics of this acid–base isotopic exchange reaction between the hydrogen atom bound to phosphorus and deuterium from the D\textsubscript{2}O solvent, was studied by means of \textsuperscript{31}P{\textsuperscript{1}H} NMR spectra for the compounds 8–10 (Figure 6).

A point to note is that the \textsuperscript{31}P and \textsuperscript{31}P{\textsuperscript{1}H} NMR spectra of 9 in D\textsubscript{2}O after 3.5 h exhibit a triplet (1:1:1) at \(d = 14.63\) ppm with a \(J(P, D)\) of 89 Hz as a result of the completed isotopic exchange, whereas no exchange was observed for 10 after 2 days in D\textsubscript{2}O. The phosphinic acid form of 1–OPH(OH)–1,7–C\textsubscript{2}B\textsubscript{10}H\textsubscript{11} disappears under isotopic exchange but the reaction is not as fast as in the case of Na[1–Me–7–OPH(O)–1,7–C\textsubscript{2}B\textsubscript{10}H\textsubscript{10}]. After 48 h in D\textsubscript{2}O, a triplet (1:1:1) at \(d = 12.96\) ppm with a \(J(P, D)\) of 87 Hz was observed.

**Acidity, \(pK_a\) comparison**

Phosphinic acids possess one acidic P–OH group; the acidity of organophosphinic acids varies in the range of 1.3–2.5 \(pK_a\).

In a similar way as carboxylic acids, \(pK_a\) values of phosphinic acids depend on the backbone molecule and the presence of other functional groups. We compared acid strengths of different carboranylphosphinic acids and their organic analogue phenylphosphinic acid. To our surprise, meta-carborane enhances the acidity of corresponding phosphinic acid compared to ortho-carborane and phenyl group (Figure 8). Also the presence of CH\textsubscript{3} group on the other C\textsubscript{6} decreases the acidity of the corresponding carboranylphosphinic acid.

**Conclusions**

This work has shown that, in a manner similar to organic phosphinates, purely inorganic carboranyl phosphinates can be prepared in very good to excellent yields. Carboranylphosphinic acids have been prepared with both isomers, ortho- and meta-carborane. The hydrogen in the H–P unit of the carboranylphosphinate has been easily exchanged by D from the deuterated NMR solvent, although rate differences have been noticed depending on the adjacent carborane carbon substituent and the salt or acid form utilized. The carborane influence has been observed in the \(pK_a\) of the phosphate, which is more negative for the meta-carboranyl than for the «comparable» phenyl and ortho-carborane. It is expected that these enhanced electronic properties will be accompanied by others derived from the hydrophobicity and space-filling efficiency of the carboranyl fragment, making the physicochemical properties of the generated metal complexes attractive for applications in medicine or in materials science.
